ATTACHMENT D7

NONDETECT UNCERTAINTY EVALUATION

THIS PAGE INTENTIONALLY LEFT BLANK

D7. NONDETECT UNCERTAINTY EVALUATION

Chemicals of potential concern (COPCs) were selected for each exposure unit (EU) in each solid waste management unit (SWMU) for those analytes that were detected above background and where maximum detected value is greater than the no action level [as defined in the Risk Methods Document (DOE 2011a) for the child residential scenario]. For those analytes that never were detected within an EU, even if the detection limit is greater than the no action level, the analyte was not considered a COPC. Uncertainties are associated with this assumption. To assist in evaluating this uncertainty, the maximum detection limit was used as an exposure point concentration, and hazard index (HI) and excess lifetime cancer risk (ELCR) were calculated for the nondetected analyses. This attachment presents the results of these calculations.

Constituents with detection limits greater than the NAL and background concentrations were screened as COPCs as previously discussed in this BHHRA. The results of the screening are presented in Table D7.1. Several constituents for COPC screening did not have toxicity factors defined in Attachment D4. Those constituents and toxicity factors are listed in Table D7.2.

Chronic daily intakes (CDIs) for noncarcenogens and carcinogens are shown in Tables D7.3 and D7.4. HI and ELCR are calculated in Tables D7.5 and D7.6, respectively. These calculations showed no hazard greater than 1 and no ELCR greater than 2×10^{-6}, which is toward the bottom of the EPA risk range (EPA 1991), for the current industrial worker.

The maximum ELCR for any constituent for the current industrial worker was 1.7×10^{-6} as a result of N-Nitroso-di-n-propylamine.[1] This constituent was not detected in any of the Soils Operable Unit samples and is not expected to be present. Further, this uncertainty evaluation looked at the maximum detection limit for the constituent (2.4 mg/kg). The minimum detection limit at this exposure unit was 0.39 mg/kg, a value that would have resulted in an ELCR $< 1 \times 10^{-6}$ to the current industrial worker.
